

This report was updated January 18, 2013, to correct errors in Tables A and 2.

## U.S. Decennial Life Tables for 1999–2001: State Life Tables

by Rong Wei, Ph.D., Office of Research and Methodology; Robert N. Anderson, Ph.D., Division of Vital Statistics; Lester R. Curtin, Ph.D., Division of Health and Nutrition Examination Surveys; and Elizabeth Arias, Ph.D., Division of Vital Statistics

### Abstract

**Objective**—This report, following publication of the national life tables (1,2) for 1999–2001, presents state-specific life tables for the 50 states and District of Columbia by race (white and black) and sex. These tables are the most recent in a series of decennial life tables for the United States.

**Methods**—Data used to prepare these state-specific life tables include population counts by age on the census date of April 1, 2000; deaths occurring in the 3-year period of 1999–2001; and counts of U.S. resident births during 1997–2001. Methods for calculating the life tables were modified from the previous decennial life tables to automate the smoothing of age-specific mortality data and to allow for the estimation of life tables for smaller population subgroups, which often had insufficient data available to estimate reliable life tables under the previous method. The current method allows for the estimation of life tables for the black population in six states, which were never previously published due to small numbers of deaths. Standard errors for estimating life expectancy and probability of dying are also presented in this report.

**Results**—Among the 50 states, Hawaii had the highest life expectancy at birth during the 1999–2001 period at 80.23 years, and Mississippi had the lowest life expectancy at 73.88 years. Life expectancy for the District of Columbia was even lower at 73.09 years. State-specific life expectancy at birth improved from the previous decennial period (1989–1991) for all states and the District of Columbia. Life expectancy at age 65 ranged from 20.42 years in Hawaii to 16.61 years in Kentucky. Life expectancy at age 65 also improved for all states except Kentucky.

**Keywords:** life expectancy • survival • death rates • state mortality

### Introduction

This report presents life tables for 1999–2001 for each of the 50 states and District of Columbia and is one of a series of reports presenting the U.S. decennial life tables for 1999–2001. The series, by the Centers for Disease Control and Prevention's National Center for Health Statistics (NCHS), also includes a report presenting U.S. national life tables (1); a report that describes in detail the methods used to estimate the national life tables (2); and a report on national life tables analyzed by major groups of cause of death (forthcoming).

Unlike U.S. national life tables, which are published both annually and decennially, state life tables are published only decennially. Each set of life tables in the decennial series is based on the decennial census of population and deaths in the 3-year period centered on the census year, (e.g., during 1979–1981, 1989–1991, and so forth). The decennial state life tables for 1999–2001 are the most recent in the series that began with the 1939–1941 period. For each of the 50 states and District of Columbia, life tables in this report are presented by race (white and black) and sex where the numbers of deaths were sufficient to produce reliable estimates.

### Data and Methods

The life tables presented in this report are based on age-specific death rates calculated using data from the 2000 census of population (as of April 1, 2000) and deaths occurring in the United States in the 3 years proximate to the 2000 census (i.e., 1999–2001). Information on all resident deaths occurring in the 50 states and District of Columbia was collected from death certificates filed in state vital statistics offices and reported to NCHS as part of the National Vital Statistics System (NVSS). The general methodology used in preparing state life tables was originally developed by Thomas N.E. Greville for the 1939–1941 decennial life tables (3),

with modifications applied by later authors for the preparation of subsequent decennial tables. In preparing the state life tables for 1999–2001, significant changes were made to the previous estimation methodology. These changes resulted in improvements in the technique for smoothing the data and in the estimation of life tables for states with small numbers of deaths (i.e., where the total number of deaths in the data period for a population is less than 700; see “[Technical Notes](#)”).

The modified methodology for smoothing the data is based on a systematic statistical procedure, which ensures that estimation is efficient and repeatable, and that the resulting mortality estimates are objective and statistically optimized. Using the previous methodology, when the age distribution of observed death rates was not sufficiently smooth, the observed death rates were then manually adjusted by transferring deaths from one age group to another adjacent age group in an iterative manner until smoothness was achieved—a time-consuming process. The current life table methodology utilizes a parametric model (4) representing the typical shape of the age-specific mortality curve. This method results in a curve that is smoothed with minimized estimation errors. Details of this method are presented in the “[Technical Notes](#).”

Another significant improvement in the methodology involved estimating life tables for race and sex groups in states with small numbers of deaths. Life table estimation for these populations is complicated by concerns about reliability due to small numbers of observed deaths (5). Life tables for the previous decennial period 1989–1991 were not published for black populations in 18 states because of this concern. The criterion for publication required the total number of deaths for a population group during the 3-year period to be greater than 700. This criterion was derived from the calculation of coefficients of variation for death rates and life expectancies (5). To further reduce the minimum criterion for estimating life tables for small populations, a method of probability modeling with historical data was used (6). NCHS has well-documented mortality data for more than 30 years, and data from the historical record can be used to assist the estimation of current death rates (6,7); see “[Technical Notes](#)” for detail on the methodology. By applying this method, the minimum number of deaths criterion was reduced to 300 deaths for the 3-year period. As a result, life tables for the black population (males and females) in six states (Iowa, Minnesota, Nebraska, New Mexico, Oregon, and Rhode Island), unpublished in previous decennial series, are published for 1999–2001. Nevertheless, there are still 11 states (Alaska, Hawaii, Idaho, Maine, Montana, New Hampshire, North Dakota, South Dakota, Utah, Vermont, and Wyoming) in which the total number of deaths is insufficient for reliable estimation (i.e., less than 300 for either black females or black males or both). Life tables for the black population for these 11 states are not published in this series.

## Explanation of life table and standard error table columns

Note: Data used for illustration are from Table IA–3 for females in Iowa.

**Column 1**—Age ( $x$  to  $x + 1$ ) in years: Shows the interval of 1 year between the two exact ages indicated. For instance, “21–22”

indicates the interval between the 21st and the 22nd birthdays; in other words, the 22nd year of life before reaching the 22nd birthday.

**Column 2**—Probability of dying between ages  $x$  and  $x + 1$  ( $q_x$ ): Shows the proportion of the members of the life-table cohort alive at the beginning of the indicated year of age who will die before reaching their next birthday on the basis of the mortality rates of 1999–2001. For example, for females (Table IA–3) who reach age 21 in Iowa, the probability of dying before reaching their 22nd birthday is 0.00042—which means that out of every 1,000 females surviving to age 21, 0.42 will die before reaching their 22nd birthday.

**Column 3**—Number surviving to age  $x$  ( $l_x$ ): Shows the number of persons, starting with a cohort of 100,000 live births, who will survive to the birthday marking the beginning of the indicated year of age. Thus, out of 100,000 female babies born alive in the cohort of Table IA–3, 99,640 will complete the first year of life and enter the second, 99,071 will reach age 21, and 74,718 will reach age 75.

**Column 4**—Number dying between ages  $x$  and  $x + 1$  ( $d_x$ ): Shows the number dying in each successive age interval out of 100,000 live births. Thus, out of 100,000 female babies born alive, 360 will die in the first year of life (ages 0–1), 41 in the 22nd year (ages 21–22), and 2,093 in the 76th year (ages 75–76). Each figure in column 4 is the difference between two successive numbers in column 3 (e.g., 41 deaths in the 22nd year are the surviving difference between 99,071 in the 22nd year and 99,030 in the 23rd year).

**Columns 5 and 6**—Person-years lived from ages  $x$  and  $x + 1$  ( $L_x$ ), and Total number of person-years lived above age  $x$  ( $T_x$ ): Both columns describe the stationary population. Suppose that a group of 100,000 persons such as that assumed in column 3 are born every year, and that the proportion dying in each such group in each age interval throughout the lives of the members is exactly that shown in column 2. If there were no migration and if the births were evenly distributed over the year, the survivorship of these births would constitute what is called a stationary population, because in such a population the number of persons living within a given age interval would never change. When a person leaves an age interval, whether by death or growing older and entering the next higher age interval, his or her place would immediately be taken by someone entering from the next lower age interval. Thus, a census taken at any time in such a stationary community would always show the same total population and the same numerical distribution of that population among the various age intervals. In such a stationary population supported by 100,000 annual births, column 3 shows the number of persons who, each year, would reach the exact age that marks the beginning of the age interval indicated in column 1, and column 4 shows the number of persons who would die each year in that year of age interval. Column 5,  $L_x$  (person-years lived between ages  $x$  and  $x + 1$ ), shows the number of persons in the stationary population in the indicated year of age. For example, the number shown in Table IA–3 for the year of age 21–22 is 99,051. This means that in a stationary population supported by 100,000 annual births, and with proportions dying in each age interval in accordance with column 2, a census taken on any date would show 99,051 persons at age 21 (i.e., between exact ages 21 and 22). Column 6,  $T_x$  (total number of person-years lived above age  $x$ ), shows the total number of persons in the stationary population in the indicated year of age and all subsequent years of age. For example, in the stationary population of persons described above, column 6 shows

that there would be at any given moment a total of 6,052,029 persons who had reached their 21st birthday. The population at age 0 and above—in other words, the total persons of the stationary community—would be 8,139,133.

**Column 7—Expectation of life at age  $x$  ( $e_x$ ):** The average remaining lifetime (also called expectation of life at age  $x$ ) at any given age is the average number of years of remaining life to be lived by those surviving to that age, on the basis of a given set of age-specific rates of dying. To relate these figures to the preceding columns of the life table, it is necessary to observe that the figures in column 5 of the life tables can also be interpreted in terms of a single life-table cohort without introducing the concept of the stationary population. From this point of view, each figure in column 5 represents the total time in years lived between two indicated birthdays by all those reaching the younger age among the survivors of a cohort of 100,000 live births. Thus, the figure of 99,071 for females in Iowa in the year of age 21–22 is the total number of years of life between their 21st and 22nd birthdays by the 99,071 (column 3) who reached their 21st birthday out of the original cohort of 100,000 females born alive. The corresponding figure (6,052,029) in column 6 is the total number of years lived after attaining age 21 by the 99,071 reaching that exact age. This number of years divided by the number of persons (6,052,029 divided by 99,071) gives 61.09 years as the average remaining lifetime at age 21 for females in Iowa.

**Standard errors (SEs)—**The probabilities of dying and the expectation of life presented in this report are “point estimates.” They do not give the reader an indication of how accurate they are. Therefore, SEs for estimates of  $q_x$  and  $e_x$  are also presented. SEs of probability of dying and of life expectancy contain six and three decimal places, respectively, and are shown in Tables IA–10 and Table IA–11 for Iowa. Nine life tables for the total population—by race, by sex, and by race and sex—are based on a complete count of resident deaths in Iowa during 1999, 2000, and 2001. As such, they are not subject to sampling error. However, even complete counts may be considered as one of a large series of possible results that could have arisen under the same circumstances. This type of variation is known as random error. The SEs shown in this report reflect random error only, not other errors such as misreporting of age on death certificates or in the census.

SEs can be used to develop confidence intervals (CIs) within which the point estimates are expected to lie with a probability level of  $1 - \alpha$ . Even though 68 percent CIs are rarely used because of their high degree of uncertainty, they are shown here to demonstrate the method of construction of CIs. To obtain a 68 percent CI for the probability of dying at any age, take the point estimate from column 2 of the appropriate life table and add and subtract one SE from the table that gives the SEs of the probability of dying [68 percent CI = point estimate  $\pm 1.00(\text{SE})$ ]. The 95 percent CI is obtained by adding and subtracting two (1.96 for exact value) SEs [95 percent CI = point estimate  $\pm 1.96(\text{SE})$ ]. For example, the probability that a 50-year-old female in Iowa will die before her 51st birthday is 0.00262 (Table IA–3) with an SE of 0.000206 (Table IA–10). Therefore, the 68 percent CI is from 0.002414 to 0.002826, and the 95 percent CI is from 0.002208 to 0.003032. The life expectancy of a 50-year-old female is 33.29 years (Table IA–3) with an SE of 0.055 years (Table IA–11); the 68 percent CI for the life expectancy is, therefore, from 33.135 to 33.345 years, and the 95 percent CI is from 33.080 to 33.400 years.

## Results and Discussion

### Life tables for the 50 states and District of Columbia

#### Complete life tables

A set of complete life tables (age interval in 1 year from 0 to 109 years) for each state and the District of Columbia is available online from “U.S. Decennial Life Tables for 1999–2001: State Life Tables” at <http://www.cdc.gov/nchs/nvss/mortality/lewk4.htm>. All table titles are listed in Table II. These tables are numbered using the FIPS alpha code for the state combined with a table code. The table code is denoted as 1 for the total population, 2 for total males, 3 for total females, 4 for total white persons, 5 for white males, 6 for white females, 7 for total black persons, 8 for black males, 9 for black females, 10 for the standard error of  $q_x$ , and 11 for the standard error of  $e_x$ . For example, Table AL–3 included in this report shows the complete life table for total females in Alabama, and Table KY–11 shows  $S^2(e_x)$  for Kentucky.

#### Summary tables for population surviving and life expectancy at 5-year intervals

Table 1 summarizes survivorship by age (in 5-year age intervals), race (white and black), and sex for the 50 states and District of Columbia. Table 2 summarizes life expectancy by age, race, and sex in the same way. Both tables are constructed by abstracting figures from column 3 ( $l_x$ ) (Table 1) and column 7 ( $e_x$ ) (Table 2) from the complete tables at age 0, 5, 10, ... , 105 years for all nine subpopulations.

#### Life expectancy at birth ( $e_0$ ) and at age 65 ( $e_{65}$ )

Life expectancy at birth ( $e_0$ ) by race and sex for the United States, each state, and the District of Columbia is presented in rank order in Table A. Figure 1 shows the geographic distribution for the United States. At the state level for the total population, Hawaii had the highest  $e_0$  at 80.23 years; Mississippi, at 73.88 years, had the lowest. The  $e_0$  in the District of Columbia was 73.09 years. Table B shows the change in  $e_0$  in rank order for the 50 states and District of Columbia between the two decennial periods 1989–1991 and 1999–2001. The District of Columbia had a substantial improvement (5.10 years)—higher than all of the states. Among the states, New York had the largest improvement during this period (3.52 years) and Wyoming had the smallest improvement (0.43 years). For race-sex specific groups, the District of Columbia had substantial improvements in all population groups (7.58, 3.25, 7.06, and 2.85 years for white males, white females, black males, and black females, respectively). Among the states, New York had the largest improvements during this period for all race-sex-specific groups (3.77, 2.46, 6.27, and 3.49 years for white males, white females, black males, and black females, respectively). Oklahoma had the smallest improvements for both white males (1.24 years) and white females (0.16 years). Kansas had the smallest improvement of all states for black males (0.99 years), while Kentucky had the smallest improve-

**Table A. Life expectancy at birth, by race and sex: United States, each state, and the District of Columbia, 1999–2001**

Rank	Area and state	Total			White			Black

**Figure 1. Life expectancy at birth: United States, each state, and District of Columbia, 1999–2001**

ment (0.33 years) for black females. Also for black females, Arkansas had no improvement, and Kansas, Mississippi, Oklahoma, Wisconsin, and West Virginia even had declines in  $e_0$  (–0.02, –0.14, –0.14, –0.93, and –1.71 years, respectively).

Sex differences in  $e_0$  are presented graphically by quartile in [Figure 2](#). Life expectancy at birth is higher for the female population in all states and the District of Columbia. The differences in  $e_0$  between females and males range from 9.03 years in the District of Columbia to 3.72 years in Wyoming.

For 39 states and the District of Columbia for which there is sufficient data to determine life tables for the black population, the differences in  $e_0$  between the white and black populations are presented by quartile in [Figure 3](#). The  $e_0$  is higher for the white population than for the black population for all states and the District of Columbia. The differences between the white and black populations in  $e_0$  range from 11.93 years in the District of Columbia to 0.26 years in Nebraska.

Life expectancy at age 65 ( $e_{65}$ ) is presented in [Table C](#) and ranges from 20.42 years in Hawaii to 16.61 years in Kentucky. [Figure 4](#) shows the change in  $e_{65}$  between the two decennial periods 1989–1991 and 1999–2001 for each state (total population). Arizona had the largest improvement (1.55 years), and Louisiana had the smallest improvement (0.40 years), while Kentucky actually had a slight decline (–0.52 years). For race-sex-specific groups, the District of Columbia had  $e_{65}$  higher than all of the states for white persons (18.88 and 22.79 years for males and females, respectively). Of the states, the highest  $e_{65}$  are 18.68 (Hawaii), 21.82 (Florida), 16.37 (Connecticut), and 20.18 (Massachusetts) years for white males, white females, black males, and black females, respectively. The lowest  $e_{65}$  are 15.35 (Mississippi), 18.34 (Kentucky), 12.63 (Louisiana), and 16.20 (Arkansas) years for white males, white females, black males, and black females, respectively.

**Table B. Change in life expectancy at birth from 1989–1991 to 1999–2001: United States, each state, and the District of Columbia**

Rank	State	Total			White			Black		
		Both sexes	Male	Female	Both sexes	Male	Female	Both sexes	Male	Female

## Technical Notes

In many ways, the methodology used to construct the decennial state life tables for 1999–2001 is similar to that used for the national tables for 1999–2001 (2). However, differences do exist in the technique for smoothing the curve for the probability of dying ( $q_x$ ). The  $q_x$  is calculated first based on the observed data (mortality counts and census populations). The distribution of  $q_x$  is then smoothed using the technique described in this report. A combination of several statistical methods is used to allow for the flexibility of smoothing. Some of these methods have been used in previous decennial life tables, and some are new applications developed for use in constructing the current state-specific tables. The new methods and those specific to construction of the state life tables are described in this report. Additional details about the general methodology used in construction of both national and state tables are available from the methodology report for the national life tables (2). Methodologies common to all state life tables are described in the text, while specific applications for individual states are described in tabular form (Table I).

### Data used for computing state life tables

The data used in preparing the 1999–2001 state decennial life tables (Table II) consist of:

- A complete count of resident deaths occurring in the United States during the 3-year period of 1999–2001. These data come from death certificates filed in state vital statistics offices and are reported to the National Center for Health Statistics as part of the National Vital Statistics System (NVSS).
- Population counts for each state on the census date April 1, 2000.
- Birth counts (also from NVSS) for each year from 1997 through 2001, inclusive.

The data are disaggregated by age, sex, and race. Race-specific tables are published for white and black populations separately, while tables for the total population include other races in addition to white and black.

Birth counts, rather than population counts, are used in calculating the denominators of the mortality rates at ages under 2 years. This is justified because census populations for ages under 2 years are believed to be underenumerated (8). Thus, birth counts may be expected to produce a more accurate estimate of the average population under age 2 during the 3-year period than is provided by the population enumerated on the census date.

With regard to census data, actuarial theory indicates that the population counts used in calculations should ideally be those as of a central date during the 3-year period, in this case, July 1, 2000. For calculation of the decennial life tables, the enumerated populations as of April 1, 2000, are used as if they were populations as of July 1. This is done to be consistent with death rates published for the United States and each state. Death rates for census years in published U.S. vital statistics use populations as of April 1 in the denominator. However, the difference between the two sets of population counts is very small.

Some preliminary adjustments were made to the data before the life tables were constructed. The description of these preliminary

adjustments is available from the methodology report for the national life tables (2). One of these adjustments is for missing age at death. No age at death was reported for 1,134 deaths out of a total of 7,211,175 (0.016 percent) deaths during 1999–2001. Age was imputed for these deaths based on the assumption that they are distributed among the various age groups in the same proportions as deaths where age is reported. The imputed ages at death used in the national tables were also used for the state tables, so no additional age imputation was needed for each state.

In six states (Iowa, Minnesota, Nebraska, New Mexico, Oregon, and Rhode Island), the total number of deaths ranged between 300 and 700 among black male or black female populations and did not meet publication criteria for estimation reliability as in previous decennial life tables (5,8). For these populations,  $q_x$  was calculated for each single year from 1970 through 2001 (6). Using these annual  $q_x$  values, a mixed probability model was then used to estimate the age-specific  $q_x$  for 1999–2001 for these populations (6).

Because of the issue of data reliability (age misreporting or small populations) for the oldest ages (i.e., ages 85 and over), the indices of the life table for ages over 85 were not derived from observed data but were extrapolated from a statistical model (see below).

### Componential smoothing methods

The life table parameter  $q_x$  is the proportion of a group of persons at exact age  $x$  in a given year who are expected to die before attaining age  $x + 1$ . The  $q_x$  is also called the probability of dying. Other parameters in the complete life table are derived from  $q_x$ , which itself depends on the number of deaths  $D_x$  and the midyear population  $P_x$  for each age interval  $x$  to  $x + 1$  observed during the calendar year of interest. The age distribution of the probability of dying should be, according to demographic and actuarial theory, regular and smooth (4). In practice, however, especially when the number of deaths is small, the observed age distribution of  $q_x$  tends to be irregular. In general, the smaller the number of deaths, the more jagged and less smooth the age distribution becomes. Therefore, smoothing procedures are often applied to observed data, including  $D_x$ ,  $P_x$ , and  $q_x$ , to achieve a more regular and smooth age distribution.

The age-specific number of deaths  $D_x$ , population counts  $P_x$ , and probability of dying  $q_x$  were smoothed by applying multiple statistical methods either separately or jointly: a) Beer's graduation technique applied to  $D_x$  and  $P_x$ ; b) the Heligman-Pollard (HP) parametric model directly applied to observed (i.e., unsmoothed)  $q_x$ ; c) the HP parametric model applied to smoothed  $q_x$  (by Beer's method); and d) locally weighted smoothing (LOESS) applied to observed  $q_x$ . Methods a, b, and d are considered one-step smoothing processes, while method c is a two-step process. Descriptions of these four smoothing methods are given in the following sections.

#### Beer's graduation technique on $D_x$ , $P_x$

For each gender and race- and state-specific population,  $D_x$  for years 1999–2001 and  $P_x$  for decennial year 2000 were smoothed separately using Beer's graduation technique. Beer's ordinary minimized fifth difference formula was applied by using Beer's multipliers on observed deaths in 5-year age intervals to get smoothed single year of age data. Similarly, Beer's multipliers were applied to

<sup>1</sup>Beer is Beer's graduation technique; LOESS is locally weighted smoothing; merge is merging smoothing results from Beer/LOESS to HPs using a transition formula; HP on data is applying the Heligman-Pollard equation on data; HP on Beer is applying the Heligman-Pollard equation on results from Beer's method; see "Technical Notes."

NOTE:  $q_x$  is the probability of dying between ages  $x$  and  $x + 1$  years.

population estimates in 5-year age intervals to get smoothed estimates for single-year age intervals.

Details of Beer's method are presented in the methodology report for the national decennial tables (2).

### Calculation of probability of dying, $q_x$ , for smoothing

The probability of dying,  $q_x$ , was calculated based on either observed  $D_x$  and  $P_x$  or Beer's smoothed  $D_x$  and  $P_x$  using the following method: For ages under 2 years, births  $E_x$  instead of  $P_x$  were used to calculate  $q_x$ . The first life table quantities to be calculated were the values of  $d_x$ , the number of deaths occurring between exact age  $x$  and  $x + 1$  in the life table cohort commencing with per 100,000 ( $l_0$ ) live births. This was calculated by the formula

$$d_x = l_0 D_x / E_x \quad x < 2 \quad [1]$$

where  $d_x$  is the estimated number of deaths per 100,000 ( $l_0$ ) births occurring in 1999–2001 between exact ages  $x$  and  $x + 1$ ;  $D_x$  is the actual death count (adjusted for nonreporting of age) in this 3-year period; and  $E_x$  is the weighted average of births for 1997, 1998, 1999, 2000, and 2001 (2).

The unrounded values of  $d_x$  were then used to calculate the number of survivors  $l_x$  up to age 2 years by successive applications of the formula

$$l_{x+1} = l_x - d_x \quad x < 2 \quad [2]$$

The probability of dying within each age category for ages under 2 years was then estimated as  $d_x$  divided by  $l_x$  as in

$$q_x = d_x / l_x \quad x < 2 \quad [3]$$

For ages 2 years and over, the following method was used to calculate  $q_x$ :  $m_x$  denotes the ratio  $d_x/L_x$ , commonly called the central death rate. Assuming a uniform distribution of deaths over the year at age  $x$ ,

$$q_x = \frac{2m_x}{2 + m_x} \quad x \leq 2 \quad [4]$$

This approximation is appropriate when the life table is constructed by single years of age and is the basis of the calculation for probabilities of dying at ages 2–85 years. Completion of the calculation depends, therefore, on the ability to calculate the central death rate  $m_x$  at different ages. To do this, different methods were used for ages 2–4 and 5–85 years, as described below.

$D_x$  denotes the adjusted number of deaths in a population category at age  $x$  (in completed years) during 1999–2001 (i.e., 3 years), and  $P_x$  denotes the population at age  $x$  in the middle of the period. The central death rate,  $m_x$ , was then computed as

$$m_x = \frac{D_x}{3P_x} \quad [5]$$

As previously noted, the populations actually used were those as of April 1, 2000.

However, because the number of deaths occurring in a single year of age during 1999–2001 was drawn from three consecutive annual population counts, it was considered that the accuracy of these  $m_x$  values would be improved by replacing  $3P_x$  in the denominator of formula 5 by the sum of the populations at ages  $x-1$ ,  $x$ , and  $x+1$ . This is because the change in the death rates in very young ages (2–4 years) is substantial across cohorts; therefore, the corresponding population count is more accurate than  $P_x$  from a centered year when used as the denominator. Thus, the formula becomes

$$m_x = \frac{D_x}{P_{x-1} + P_x + P_{x+1}} \quad [6]$$

The combination of formulas 4 and 6 is equivalent to the single formula

$$q_x = \frac{D_x}{P_{x-1} + P_x + P_{x+1} + \frac{1}{2}D_x} \quad 2 \leq x \leq 4 \quad [7]$$

where the values of  $D_x$  and  $P_x$  were obtained from either observed data or interpolated data using Beer's graduation technique. This formula was used for ages 2–4 years.

The combination of formulas 4 and 5 is equivalent to

$$q_x = \frac{D_x}{3P_x + \frac{1}{2}D_x} \quad 5 \leq x \leq 85 \quad [8]$$

This formula was used for ages 5–85 years, and the values of  $D_x$  and  $P_x$  were also obtained by using either observed data or Beer's interpolation. The last age for the Beer's smoothed  $q_x$  was 79 years, because older age groups could not be interpolated without data for ages over 85.

### Smoothing with Heligman-Pollard equation, extrapolating $q_x$ to 130 years

In a recent study using vital statistics mortality data, the Heligman-Pollard (HP) equation was found to fit well with current U.S. age-specific mortality (9). The HP equation is a nonlinear model consisting of three components and eight parameters:

$$\frac{q_x}{1 - q_x} = A^{(x+B)^C} + D \exp[-E(\log x - \log F)^2] + GH^x \quad [9]$$

where parameters  $A$ ,  $B$ , and  $C$  in the first term of the equation measure mortality in the first year of life, the rate of change in mortality from birth to the first year of life, and the rate of mortality decline in childhood, respectively. The second term of the equation describes mortality for ages in the middle of the life span (approximately between ages 10 and 40 years), where a so-called "accident hump" often appears, and parameters  $D$ ,  $E$ , and  $F$  measure respectively the location, width, and height of this accident hump. Parameters  $G$  and  $H$  in the third term measure mortality change in the oldest ages of the life span (4).

In constructing the national decennial life tables, only the third term ( $GH^x$ ) of the HP equation was used to smooth and extrapolate  $q_x$  at ages 65 and over (2). Because the observed  $q_x$  values in the national tables were based on large numbers of deaths, Beer's graduation technique was deemed sufficient as a smoothing method for the younger ages. In contrast, the state life tables are based on much smaller numbers of deaths and, thus, Beer's technique was not always sufficient alone to obtain a smooth  $q_x$  distribution by age. To enhance the smoothness of  $q_x$  in the state life tables, the following procedure was used: First, a two-step approach was applied using the complete HP equation to fit Beer's smoothed  $q_x$  from ages 0 to 79 years, and then  $q_x$  was extrapolated to age 130 years using the method described in the following paragraph. Second, the HP model was applied to the observed  $q_x$  directly. This one-step smoothing procedure was applied to  $q_x$  for ages 0–85 years, and then the smoothed  $q_x$  were extrapolated to age 130. Both one- and two-step smoothing results for  $q_x$  were compared with the observed  $q_x$  by using plots, and the one with the better fit (i.e., with smaller errors) was selected for constructing the final life tables.

Using the HP model,  $q_x$  was estimated for all ages up to 130 by extrapolation. However, in the final life tables, estimates were truncated to age 109. This is consistent with the method used for calculation of the national life tables and for previous decennial life tables. The extrapolation formula is

$$\hat{q}_x = \frac{\hat{A}^{(x+\hat{B})^{\hat{C}}} + \hat{D} \exp[-\hat{E}(\log x - \log \hat{F})^2] + \hat{G}\hat{H}^x}{1 + \hat{A}^{(x+\hat{B})^{\hat{C}}} + \hat{D} \exp[-\hat{E}(\log x - \log \hat{F})^2] + \hat{G}\hat{H}^x} \quad [10]$$

where  $\hat{A}$  to  $\hat{H}$  were estimated from equation 9 with an error term allowed.

## Locally weighted smoothing

The locally weighted smoothing (LOESS) procedure was applied using the SAS/LOESS procedure (SAS, 2008). In contrast to Beer's method, which uses a smoothing window containing 25 adjacent ages, the size of the smoothing window in LOESS is flexible; therefore, the degree of smoothness is flexible and can be applied differently to individual states according to the age-specific pattern observed in the data. For the state life tables, this method was applied in smoothing  $q_x$  for the younger ages, from 0 to 35 years, for populations in which the mortality change from age to age is substantial, rendering the results of Beer's method unsatisfactory. The size of the smoothing window was varied by using 5 percent, 8 percent, 10 percent, and 12 percent of the age range. The LOESS method was also applied to  $q_x$  values for the black population of six small states in which the mortality rates  $q_x$  for ages with zero observed deaths were estimated using historical data (see next section).

## Small states: Estimating $q_x$ with probability model and 32 years' mortality data

A mixed probability model was used to estimate  $q_x$  for states with population subgroups having between 300 and 700 deaths. This model uses observed data for previous years to estimate  $q_x$  values for ages for which there are no deaths or insufficient deaths to calculate a reliable estimate. NCHS has well-documented mortality data dating from 1968. In these cases,  $q_x$  was estimated using mortality data from 1970 to 2001. A mixed probability distribution model which includes two probability components, a discrete component specified at 0, and a continuous component for values greater than 0, was used to estimate  $q_x$  in the current life table based on 32 years' data.

Let  $Y$  represent age-specific mortality rates, a natural model for  $Y$  is a mixed probability distribution model where  $Y = 0$  with probability  $1 - p$ , where  $0 < p < 1$ ; otherwise, for positive rates,  $Y$  follows a continuous distribution with cumulative distribution function (cdf)  $F(y; \theta_1)$ , with  $\theta_1$  representing a vector of parameters. The distribution of  $Y$  is a mixture of discrete and continuous components, as in

$$P(Y \leq y) = Gm(y; p, \theta_1) = (1 - p)H(y) + pF(y; \theta_1) \quad [11]$$

where  $H(y)$  is a step function:

$$H(y) = \begin{cases} 0, & y < 0 \\ 1, & y \geq 0 \end{cases}$$

The corresponding generalized probability density is

$$g_m(y; p, \theta_1) = (1 - p)^{1 - I(y > 0)} [pf(y; \theta_1)]^{I(y > 0)} \quad y \geq 0 \quad [12]$$

where  $f(y; \theta_1)$  is a probability density function conditional on  $Y > 0$  and corresponding to  $F(y; \theta_1)$ ,  $I(A) = 1$  if  $A$  occurs, and  $I(A) = 0$  if  $A$  does not occur. The goal is to estimate the mean of the mixed distribution,

$$E(Y) = pE(Y | Y > 0) \quad [13]$$

which is a function of  $\theta \equiv (p, \theta_1)$ . Observe that equation 13 is a product of two factors,  $p$  and  $\alpha \equiv E(Y | Y > 0)$ , corresponding to the two distribution components. Equation 13 can be estimated using

the maximum likelihood estimates of  $p$  and  $\alpha$ , as in a mixed lognormal, or by regressing each of the two factors on covariates and then taking the product of the two regressions, as in two-part Hurdle or zero-inflated models (6). With this estimator, the confidence interval bands can help determine the reliability of the estimated death curve.

## Selecting smoothed curve sections of $q_x$ for different ages; merging selected sections into final $q_x$ curve for whole life span (0–130 years)

Smoothed  $q_x$  curves from all methods were plotted against the observed  $q_x$ , and the one with the best fit was selected for specific age sections. Selected  $q_x$  curves from each age section were merged to form the final  $q_x$  curve from ages 0 to 130 years. To merge two curve sections, a graduating process was applied using

$$q_x^F = \frac{1}{b-a} [(b-x)q_x^A + (x-a)q_x^B] \quad [14]$$

where  $q_x^F$  is a merged (final) curve section,  $q_x^A$  is the section with younger ages, and  $q_x^B$  is the section with older ages. For example, suppose  $q_x^A$  for ages 0 to 13 years smoothed by Beer's graduation technique is merged with  $q_x^B$  for ages 7 years and over smoothed by the HP method. For the overlapping ages (7 to 13 years), the final  $q_x^F$  would be calculated as

$$q_x^F = \frac{1}{14-6} [(14-x)q_x^A + (x-6)q_x^B] \text{ for age } x = 7, 8, 9, 10, 11, 12, 13$$

To check and ensure the fidelity of the smoothed  $q_x$ , the final composite  $q_x$  curve was plotted against the observed data for all populations. The final  $q_x$  composition for sex- and race-specific populations for every state is given in Table I, and examples (Iowa) of plots of final  $q_x$  compared with observed data are shown in Figures Ia and Ib.

## Computing $q_x$ for total, total white, and total black populations based on corresponding sex-specific populations

Data for each state consist of composite values of the population according to sex and race. Figures for the total U.S. population were computed by combining data for all males and females. Figures for the total white and total black populations were similarly computed by combining males and females for the respective race groups. The parameter  $q_x$  in each state's six sex-specific populations was smoothed (using the methods previously described) prior to creating  $q_x$  values for the three groups with both sexes combined (all races total, total white, and total black populations) for each state. For consistency, the death number  $D^T$  and population denominator  $P^T$  were computed from two separately smoothed sex-specific populations rather than directly smoothing the data for the combined deaths and populations. We denote the combined, female, and male populations using superscripts  $T$ ,  $F$ , and  $M$ , respectively. Then the number of deaths and population for the combined population is

$$D_x^T = \frac{q_x^F P_x^F}{1 - 0.5 q_x^F} + \frac{q_x^M P_x^M}{1 - 0.5 q_x^M} \quad [15]$$

Figure I. Smoothed  $q_x$  compared with observed  $q_x$ : Iowa, 1999–2001

$$P_x^T = P_x^F + P_x^M \quad [16]$$

where  $P_x^F$  and  $P_x^M$  are population sizes after smoothing, and  $q_x^F$  and  $q_x^M$  are the smoothed  $q_x$  for the corresponding female and male populations. Then,  $q_x$  for the combined population is computed as

$$q_x^T = \frac{D_x^T}{P_x^T + 0.5D_x^T} \quad [17]$$

for ages under 80, and

$$q_x^T = \frac{P_{76-79}^F}{P_{76-79}^T} q_x^F + \frac{P_{76-79}^M}{P_{76-79}^T} q_x^M \quad [18]$$

for ages 80 and over,

where  $P_{76-79}^F$ ,  $P_{76-79}^M$  and  $P_{76-79}^T$  are sums of population size across ages 76 to 79 for females, males, and total population, respectively. The two ratios of population size in equation 18 serve as weights for combining  $q_x^F$  and  $q_x^M$  into  $q_x^T$  for ages 80 and over. The  $q_x^T$  curves for combining populations calculated by this method are smooth because  $q_x^F$ ,  $P_{76-79}^F$ ,  $q_x^M$  and  $P_{76-79}^M$  are smoothed results from gender-specific populations. To ensure the quality of estimated  $q_x^T$  in this way,  $q_x^T$  curves were also plotted against the observed  $q_x^T$ . An example (Iowa) of such a plot is shown in Figure 1c.

### Calculation of remaining life table functions: $d_x$ , $l_x$ , $L_x$ , $T_x$ and $e_x$ for all populations

Once the final smoothed  $q_x$  for each age was determined from age 0 to 130 years, the rest of the life table functions were derived from  $q_x$ .

The initial life table population  $l_0$  at birth is traditionally 100,000. The remaining life table functions were then estimated based on the following equations:

Number of persons dying between ages  $x$  and  $x + 1$ :

$$d_x = l_x q_x \quad [19]$$

Number of persons alive (survivors) at the beginning of each age interval:

$$l_{x+1} = l_x - l_x q_x \quad [20]$$

Number of persons living between ages  $x$  and  $x + 1$ :

$$L_x = 0.5 (l_x + l_{x+1}) \quad [21]$$

Number of person-years lived after age  $x$ :

$$T_x = L_x + T_{x+1}, \text{ with } T_{end} = L_{end} \quad [22]$$

Average remaining lifetime (or life expectancy) at age  $x$ :

$$e_x = T_x / l_x \quad [23]$$

Finally, all life table functions were estimated through age 130 but were truncated to age 109 for the purposes of tabulation.

### Decimal places, rounding of numbers

Traditionally, published life tables show life table functions such as  $l_x$ ,  $d_x$ ,  $L_x$ , and  $T_x$  rounded to whole integers. However, because the U.S. total population is nearly 300 million, the accuracy of the life table functions extends beyond the hypothetical population of 100,000. Therefore, all life table calculations were carried out using

floating point precision, allowing for fractional deaths and fractional years of life lived. This creates a problem for users who want to reproduce the life table estimates from the rounded numbers in the tables.

Thus, users of the decennial life tables are cautioned that the life table calculations are based on additional significant digits than shown, and back-calculation using the rounded numbers cannot be expected to reproduce the exact published results.

### Calculation of standard errors of $q_x$ and $e_x$

Standard errors (SEs) for the decennial life table functions, specifically for the probabilities of dying and for life expectancies, were calculated based on an assumption that the age-specific deaths follow a binomial distribution. It is important to consider that these SEs reflect only stochastic variation. Stochastic variation is not the only source of error for life table functions; measurement error, such as age misstatement on death certificates or on census reports, also affects the accuracy of life table functions. While the extent of measurement error on life table functions has not been quantified, it is generally thought that measurement errors may be larger than stochastic errors (8). The SEs presented are rather small because the life tables for the United States and each state are based on relatively large numbers of deaths. Errors from the smoothing procedure on  $q_x$  are not given or included in standard error calculation here. Smoothing involved a complicated multiple method and stage procedure. Incorporating these methods into the estimation of the SEs would be unnecessarily complex. Any error introduced by smoothing would be very small compared with the stochastic variation and can, therefore, be safely ignored.

A binomial distribution assumption yields the following estimate for the variance of  $q_x$  (11):

$$S^2(q_x) = \frac{q_x^2(1 - q_x)}{D_x} \quad [24]$$

where  $D_x$  is the age-specific number of deaths and  $q_x$  is the probability of dying. For ages under 80,  $D_x$  is the age-specific number of deaths from vital statistics data, smoothed by interpolation and adjusted for the number of deaths with missing ages. For ages 80 and over,  $D_x$  was calculated based on the extrapolated estimate of  $q_x$ :

$$P_x = \frac{(P_{x-1} - 0.5D_{x-1} / 3)(2 - q_x)}{2} \quad [25]$$

$$D_x = \frac{3q_x P_x}{1 - 0.5q_x} \quad [26]$$

Note that  $D_x$  is the number of deaths in a 3-year data collection period (1999–2001), and  $P_x$  is the population at age  $x$  in the middle of this period.

For the variances of life expectancies at ages 0–109 years, an equation from Chiang (11) with a slight modification was used (8):

$$S^2(e_x) = \frac{l_{end}^2 S^2(e_{end}) + \sum_{y=x}^{end-1} l_y^2 (e_{y+1} + 0.5)^2 S^2(q_y)}{l_x^2} \quad [27]$$

where the “end” age is the age 1 year before the life expectancy becomes zero for the population. For all populations, this end age falls into a range between 109 and 120 years. An approximate estimation for the variances of life expectancy at the end age is:

$$S^2(e_{end}) = \frac{S^2(q_{end})}{q_{end}^4} \quad [28]$$

This is based on the relationship between  $e_x$  and  $m_x$  at the end age. That is,  $e_{end} = 1/m_{end} = (2 - q_{end})/2q_{end}$ . A linear approximation of  $S^2(e_x)$  at the end age gives  $S^2(e_{end}) = (\partial[(2 - q_{end})/2q_{end}]/\partial q_{end})^2 S^2(q_{end})$ . The  $S^2(q_x)$  and  $S^2(e_x)$  were calculated until the end age but truncated at age 109 for the published life tables.

All  $S^2(q_x)$  and  $S^2(e_x)$  were published in tables corresponding to the state-specific life tables that they describe.

**Contents**

Abstract . . . . .	1
Introduction . . . . .	1
Data and Methods . . . . .	1
Explanation of life table and standard error table columns . . . . .	2
Results and Discussion . . . . .	3
Life tables for the 50 states and District of Columbia . . . . .	3
References . . . . .	9
List of Detailed Tables . . . . .	9
Technical Notes . . . . .	52

**Acknowledgments**

The authors are grateful to Benjamin Kedem and Anastasia Voulgaraki of the University of Maryland's Mathematics Department for their support in research on modeling extreme death rates; to Jiraphan Suntorncost, Shaun Garin, and Flor M. Garay for their assistance in editing tables and checking for errors in Excel files; to Van Parsons, Meena Khare, Donald J. Malec, Julia Holmes, and Ryne Paulose for their comments and suggestions on the draft report; and to Donna Hoyert for her assistance in posting the detailed life tables online. This report was prepared for the Division of Vital Statistics under the general direction of Charles J. Rothwell, Director of Vital Statistics, and Robert N. Anderson, Chief of the Mortality Statistics Branch. Registration Methods staff and Data Acquisition and Evaluation Branch staff provided consultation to state vital statistics offices regarding collection of the death certificate data on which this report is based. This report was edited and produced by CDC/OSELS/NCHS/OD/Office of Information Services, Information Design and Publishing Staff: Jane Sudol edited the report; typesetting was done by Jacqueline Davis, Annette Holman, and Zung T. Le; and graphics were produced by Jesse Guay (contractor).
