Trends and Variations in First Births to Older Women, 1970-86

Series 21
Data From the
National Vital Statistics System
No. 47

Trends and variations in first-time childbearing by women in their thirties and older are presented for the years 1970-86. The report focuses on the decline in childbearing by women in their twenties, particularly well-educated women, and the extent to which these women have delayed motherhood. Maternal and infant health characteristics are also discussed. The information presented is drawn from the live birth certificates of all States and the District of Columbia.

Trends and Variations in First Births to Older Women, United States, 1970–86

by Stephanie J. Ventura, A.M., Division of Vital Statistics

Introduction

First births to women in their thirties have increased substantially since 1970, doubling, tripling, and quadrupling their levels in a 16-year period. Throughout the 1970's, the increases were largest for women aged 30–34 years (NCHS, 1982). Since 1980, the impact of this phenomenon has shifted to older women. Between 1980 and 1986, the increases in first births and first-birth rates were much greater for women aged 35–39 years.

The number of first births to women aged 30–34 years rose from 42,404 in 1970 to 112,964 in 1980 and then to 181,504 in 1986. Increases in births to women aged 35–39 years were also substantial, although the numbers are considerably smaller: 11,704 in 1970, 18,241 in 1980, and 44,427 in 1986 (table 1).

The first-birth rate for women aged 30–34 years increased from 7.3 births per 1,000 women in 1970 to 12.8 in 1980 and to 17.5 in 1986, an overall rise of 140 percent. The rate for women aged 35–39 years rose from 2.1 in 1970 to 2.6 in 1980 and to 4.7 in 1986, an increase of 124 percent (table 2).

During this period of rapidly rising first-birth rates for women in their thirties, rates for women in their teens and early twenties were declining.

The first-birth rate for women 15–19 years of age fell 23 percent, from 53.7 per 1,000 in 1970 to 41.4 in 1976, with the decline proceeding at a much slower pace during the rest of the 1970's and early 1980's; the rate for 1986 was 39.1 (table 2). Similarly for women in their early twenties, the first-birth rate dropped rapidly through the mid-1970's, from 78.2 in 1970 to 52.9 in 1976, a decline of 32 percent; since 1976, the rate has fluctuated between 52.4 and 57.3.

The trend in the first-birth rate for women aged 25–29 years has followed a middle course between their younger and older counterparts. The rate fell 6 percent from 1970 to 1972, then increased 33 percent during the years 1972–81, from 29.2 to 38.8. The rate has changed very little since 1981; in 1986 it was 38.8.

The first-birth rate for women in their early forties has been very low throughout this period and was relatively unchanged until 1980. From 1980 to 1986 the rate increased from 0.3 to 0.6 first births per 1,000 women in this age group. As a consequence of these varying shifts in first-birth rates by age of mother, women aged 30 years and

older are accounting for a much larger share of first births in the mid-1980's than in 1970: 15 percent in 1986 compared with 4 percent in 1970 (table 3).

The increases during the early 1970's in first-time childbearing by women in their thirties occurred at the same time that there were steep reductions in higher order birth rates or, to put it another way, a decline in large families. In the 5 years from 1970 to 1975, rates for fourth and higher order births for women aged 30 years and older fell by about one-half. As a consequence of these declines and the slowly increasing first-birth rates, the overall birth rate for these women dropped during the early 1970's, from 73.3 to 52.3 for ages 30–34 years and from 31.7 to 19.5 for ages 35–39 years (table 4).

The reversal of these declines beginning in the mid-1970's is associated entirely with the sizable increases in first-birth rates, while higher order rates continued to decline but at a slower pace. Higher order births comprised a much smaller proportion of all births to women aged 25–39 years in 1986 than in 1970 (table 5).

Clearly large numbers of women have reached age 30 years and older without having had their first child. For example, one-fourth of all women aged 30–34 years at the end of 1986 were still childless. However, national data from the June 1987 Current Population Survey indicate that only 10 percent of women in their early thirties expect to remain childless (U.S. Bureau of the Census, 1988a). The question that remains is to what extent those women who intend to have children will actually have the children they expect to bear. Related data from the National Survey of Family Growth conducted by the National Center for Health Statistics (NCHS) indicates that many of these women may ultimately remain childless because of physiological impairments in their ability to conceive and bear children (Mosher and Bachrach, 1982). These impairments tend to rise sharply with age. Until those women now in their thirties have reached the postchildbearing ages, it will not be possible to say how much of today's delayed childbearing will be made up.

Trends in first-time childbearing by age have been affected by changes in the female population of childbearing age and by changes in the various measures of fertility, including first-birth rates and birth probabilities (first-birth

rates computed for childless women) by age and the proportion of childless women (women at risk of having a first birth). These factors will be described and discussed in detail in the text and the accompanying figures and tables. Because the factors associated with these trends differ by race, the discussion in the following sections will consider each group separately. Where available, data are given for white and black women rather than white and all other women. However, the birth probabilities and the proportions childless shown in figures 1-4 are available only for white and all other women.

This report also describes the impact of trends in the educational attainment of the mother and in nonmarital childbearing on postponed childbearing. Some of the interest associated with delayed first births has focused on the possible deleterious health consequences for mother and child. Selected data (on low birth weight and prenatal care) relating to these concerns are also presented. These data indicate that the higher educational attainment of older, first-time mothers is probably the key factor offsetting these health risks.

Demographic patterns

Female population

A growing proportion of women in their late twenties and early thirties is unmarried (figure 5); many have never married, and a growing fraction is unmarried as a consequence of divorce. In 1986, for example, nearly one-third of 25–29-year-old white women and more than one-half of women of all other races were unmarried, more than double the proportions observed in the early 1960's.

The dramatic increases in the proportions of women who had had no children by ages 25, 30, or even 35 years is described in the next section. In addition to these increases, there has been a rapid rise in the number of women in these age groups (table 6). Between 1970 and 1986 the number of women aged 30–34 years increased 78 percent; the increases for women aged 25–29 and 35–39 years were 60 and 66 percent, respectively. In contrast, the number of women in their early twenties increased by only 20 percent, and the number of teenagers actually declined by 3 percent. These changes reflect the dramatic changes in fertility observed between 1946 and 1972. The large number of female babies born immediately after World War II through the late 1950's are now women aged 25–39 years.

From the early 1960's until the early 1970's, there was a sharp drop in fertility, reflected during recent years in a reduction in the number of women aged 15–19 years and 20–24 years.

Beginning in the mid-1970's there was a convergence of the rapidly increasing number of women in their thirties together with an even more sharply increasing rate of childlessness among these women. These two factors combined to produce the largest number of women ever "at risk" of having their first child. Virtually all national surveys of birth expectations among American women have shown that very few women intend or wish to be permanently childless. Therefore, it was perhaps inevitable that the effect of these simultaneous trends would be to increase first-birth rates among women in their thirties (Mosher and Bachrach, 1982; U.S. Bureau of the Census, 1988a). This is, in fact, what happened.

Childlessness, first-birth rates, and probabilities

Figures 1 and 3 show the trends in first-birth rates and probabilities of first births among women in the age groups

Figure 5. Percent of women unmarried at ages 25–29 years and 30–34 years, by race: United States, 1970–86

25–39 years. The first-birth rate relates the number of first births to all women in an age-race group regardless of their parity (the number of children they have had). The first-birth probability is a refinement of the first-birth rate in that it relates first births only to childless women (also referred to as zero-parity women), that is, the women “at risk” of having a first birth.

Birth rates rose fairly evenly for white women in the age groups 25–39 years from 1973 to 1980, although the pace of the increase was clearly greatest for women aged 30–34 years (figure 1). Since 1980, rates have completely leveled off for women aged 25–29 years, while rates for women in their thirties have continued to increase. In the case of women aged 35–39 years, the increase in recent years has outpaced that measured in the late 1970’s.

The incidence of childlessness among white women at various ages has also increased sharply since 1970 (figure 2). Among 25-year-old women the proportion childless reached a record high 55 percent by the end of 1986, compared with 35 percent in 1970. Similarly, the proportion childless among white women aged 30 years rose to 33 percent by the end of 1986 compared with 14 percent in 1970, and for 35-year-old white women, 22 percent at the end of 1986 compared with 9 percent in 1970. In sum, an unusually high proportion of women were “eligible” or “at risk” of having a first baby.

The first-birth probability for 25–29-year-old white women, on the other hand, declined slowly but fairly steadily from 1975 to 1986 after an initial rapid decline in the early 1970’s. Thus since 1980 the first-birth rate for women in their late twenties leveled off because of a decline in the birth probability (for childless women) and because the proportion of women with no children was relatively stable.

First-birth probabilities for white women aged 30–34 and 35–39 years have increased in recent years, following declines in the early 1970’s. Since 1980 the increase for women aged 35–39 years has been particularly sizable; for those aged 30–34 years it has been more modest. The increases in first-birth rates for white women in their thirties are the result of the combined effect of increased proportions of childless women and the increases in first-birth probabilities.

The rate for 30–34-year-old women increased at a slightly slower pace because the probability of a first birth for these women increased less. This indicates a gradual but clear shift to older ages in the making up of some postponed or delayed first births. Whereas in the 1970’s the first-birth rates were increasing most for women in their early thirties and increasing even for women in their late twenties, since 1980 the rates have leveled off for women aged 25–29 years and have continued to increase for women in their thirties, at a slower rate for women aged 30–34 years and more rapidly for women aged 35–39 years. As already pointed out, the question that cannot be answered for at least another decade is the extent to which these women will actually make up the births that they have delayed.

The number of first births to white women in their thirties has risen substantially during these years because of the rapid increases in first-birth rates and in the numbers of women in these age groups. The number of white women aged 30–34 years increased 71 percent from 5,085,000 in 1970 to 8,702,000 in 1986; the number aged 35–39 years rose by 63 percent, from 4,933,000 in 1970 to 8,031,000 in 1986 (U.S. Bureau of the Census, 1982, 1988b). For white women aged 30–34 years, the increase in the number of first births in the 1970’s was much greater than in more recent years, but overall there were more than four times as many births to these women in 1986 as in 1970 (155,261 compared with 36,902). For women in their late thirties, the increase has been greater in the 1980’s than in the previous decade; overall, the number born in 1986 was more than three times the number in 1970 (37,450 compared with 10,078) (table 1).

In summary, the number of first births to white women in their thirties has increased since the early 1970’s because of increases in three measures: The proportion of women at risk of having a first birth (the proportion childless), the probability of a first birth among these women, and the number of women in these age groups. The increases in the numbers of first births to women in their thirties and older have occurred during a period of relatively little increase in first births to mothers of all ages combined. Mothers aged 30 years and older now account for a much larger proportion of all first births than in any recent year (15 percent in 1986 compared with 4 percent in 1970) (table 3).

Trends in delayed childbearing among mothers of “all other” races have been affected by the changing racial composition of this population since 1970. While black women still comprise the overwhelming majority of this population (nearly 80 percent), the proportion of black women has declined during this period from 89 percent in 1970 to 79 percent in 1986 (U.S. Bureau of the Census, 1982, 1988b). The remaining 10–20 percent of the population of all other races is American Indian and Asian. In the period covered by the study, the Asian population in particular has increased sharply. Because the fertility patterns of black and American Indian women differ markedly from those of most Asian women, the factors affecting the trends for “all other” women as a group are often offsetting.

Teenage childbearing is relatively common for black and American Indian women compared with Asian women; among babies born in 1986, 23 percent of black infants and 19 percent of American Indian infants were born to teenage mothers compared with only 6 percent of Asian infants. In contrast, only 19 percent of black and American Indian births were to mothers aged 30 years and older compared with 41 percent of Asian births. Furthermore, very few first births to Asian mothers were born to teenagers, only 10 percent in 1986 compared with 41–42 percent of American Indian and black births. In contrast, 27 percent of all Asian first births and 39–41 percent of Chinese and Japanese first births were to mothers aged 30 years and older, much higher levels of childbearing by older mothers than observed for any other racial group. Only 6–8 percent of

American Indian and black first-time mothers were aged 30 years and older. In other words, a much larger proportion of black and American Indian mothers are beginning childbearing at young ages, whereas Asian mothers are much more likely to be delaying their first births. Clearly, mothers of "all other" races are not homogeneous in their childbearing characteristics.

The trends in first-birth rates, probabilities, and proportions childless can be briefly summarized for all other women as a group. First-birth rates for all other women aged 25–39 years have increased fairly steadily beginning in the early 1970's (figure 3, table 2). Since 1980, the rates for women aged 25–29 and 30–34 years have increased at a slower pace, while the rate for women aged 35–39 years has risen more rapidly. The first-birth probabilities also increased during the 1970's. However, since 1980 the probability for women aged 25–29 years has declined; for women aged 30–34 years, it has continued to rise but more slowly; for 35–39-year-old women, it has risen more steeply.

As shown in figure 4, the proportions of childless women of all other races declined steeply for women aged 35 years and 40 years over most of the period 1970–86 while increasing for 25-year-old women; for 30-year-old women the proportion childless declined until the late 1970's and has risen since 1979. In 1987 only 6 percent of 35-year-old women and 5 percent of 40-year-old women were childless, compared with 35 percent of 25-year-old women and 14 percent of 30-year-old women. First-birth rates for all other women aged 30 years and older, especially those 35–39 years, have risen because the probabilities for those women at risk of a first birth have increased and the number of women in these age groups has grown. These increases have been large enough to compensate for the sharp reduction in the proportion of childless women. The drop in childlessness among older women of all other races reflects the high proportion of black and American Indian women who began having children at relatively young ages (and are therefore not childless) combined with the apparently high rate of first-time childbearing by Asian mothers in their thirties. In 1986 the first-birth rate for women of all other races excluding black women was 30.4 for women aged 30–34 years and 9.5 for women aged 35–39 years. Both rates were nearly three times the comparable rates for black women (11.2 and 3.5, respectively) and nearly two times the rates for white women in the same age groups (18.0 and 4.9).

Educational attainment of mother

The educational attainment of women aged 25–39 years who were having their first child rose sharply during the 1970's. The proportion of these mothers who had completed some college (that is, 13–15 years of educational attainment) rose as did the proportion who were college graduates. Since 1980, the proportion with at least 1 year of college has continued to rise, but the proportion with college degrees has increased only for first-time mothers

aged 35–39 years, from 44 percent in 1980 to 53 percent in 1986 (table 7).

The educational attainment of the U.S. population as a whole has also increased during this period. However, the level among first-time mothers has continued to exceed that of the general population. Among all women aged 30–34 years, for example, the proportion with college degrees increased from 16 percent in 1975 to 24 percent in 1986 (U.S. Bureau of the Census, 1976, 1977, 1988c). Among women of the same age who gave birth to their first child during those years, this proportion increased from 40 percent to 48 percent. Similarly, among all women aged 35–39 years, the proportion with college degrees increased from 12 to 23 percent in this period, while the comparable proportion among first-time mothers rose from 32 to 53 percent.

Some of the rise in educational attainment among first-time mothers can clearly be associated with the general increase in educational attainment of the population during this period. But the far higher level of college completion among the first-time mothers probably reflects the particular characteristics of those postponing motherhood as well as a greater increase in first-birth rates among these women than among their lesser educated counterparts. First-birth rates by age and educational attainment of mother are shown in table 8 for 1970, 1975, 1980, and 1985, years for which the necessary population data were available. These rates indicate that the decline among 20–24-year-old women was especially pronounced among those who have completed college. There were substantial reductions in first-birth rates during the early 1970's for all educational attainment groups, but the only decline that has persisted since 1975 has been for women who have completed college, suggesting that these women are devoting themselves to their careers and are continuing to delay marriage and childbearing.

First-birth rates for 25–29-year-old women increased between 1975 and 1985 for all except those who had completed 4 years of college. Among the latter group, the rate dropped. These women also were evidently postponing marriage and childbearing.

The pattern of making up of postponed childbearing is most evident among women in their thirties. First-birth rates for these women have increased sharply since 1970, especially since 1975. Among women who had completed college, the increases in first-birth rates from 1975 to 1985 were 77 and 96 percent, respectively, for women aged 30–34 and 35–39 years. In summary, women in their thirties giving birth for the first time are increasingly well educated, and increasing proportions of well-educated women in these age groups are giving birth.

When the first-birth rates by age and educational attainment are examined for white and black women separately, it is apparent that well-educated women in both groups have postponed childbearing, and that they are making up for at least some of the delays at a growing pace (table 9). The main difference is that the increases for white

women in their thirties have been for all those with 1 or more years of college, while the increases among comparably aged black women have been concentrated among those with 1–3 years of college. Rates for black women with college degrees have risen less or even declined.

Nonmarital childbearing

Childbearing by unmarried women of all ages has increased at a rapid rate since the mid-1970's. Birth rates for unmarried teenagers have risen steadily and are now higher than ever; in contrast, rates for older mothers had declined by as much as 35 percent between 1970 and 1975 and have since returned to about the 1970 levels (table 10). Rates for first births for unmarried women have increased even faster than for all births. For example, the first-birth rate for unmarried women aged 30–34 years rose 47 percent in the period 1980–86, from 4.5 to 6.6 per 1,000 women, while the overall rate for this age group increased 27 percent. The increases for 35–39-year-old unmarried women had a similar pattern (tables 10 and 11).

The effect of the rising birth rates for unmarried women has been accentuated by the rapid growth in the population of unmarried women, as explained earlier. The number of women in their thirties has increased and the proportion that is not married has risen as well. As a consequence the total number of births to unmarried women in their thirties more than tripled between 1975 and 1986, and the number of first births to these women increased more than sixfold (table 12). For example, 74,928

babies were born to unmarried women aged 30–34 years in 1986 compared with just 19,800 in 1975. The number of first births to these unmarried women also increased, from 3,000 in 1975 to 18,178 in 1986.

The racial differential in the rate of nonmarital childbearing declines with increasing age, but the rate for black women is more than twice the rate for white women even at ages 30 years and older. However, if the basis for comparison is restricted to unmarried women having their first child, the racial differential is reduced. For example, the racial differential in the overall birth rate for unmarried women aged 30–34 years in 1986 was 2.7 compared with 1.6 for first-birth rates. Rates for unmarried women in both racial groups have increased in recent years, but the increases have been much larger for white than for black women, thereby reducing the racial differential.

It is difficult to account for the rising trend in nonmarital childbearing by relatively older women. Presumably, many of these women have chosen to become mothers even though they are single. Data for 1986 on the educational attainment of mothers according to marital status suggest that although unmarried mothers are not as well educated as their married counterparts, still about 30 percent had completed at least 1 year of college and about 10 percent were college graduates. The incidence of mistimed or unwanted births among well-educated women would be expected to be relatively low. More research is needed to determine the factors associated with the rising rates of childbearing by older unmarried women.

Maternal and infant health

Low birth weight

The proportion of babies weighing less than 2,500 grams (5 pounds, 8 ounces) at birth is a widely used measure of birth outcome which in turn is highly correlated both with infant morbidity, including congenital anomalies, and with infant mortality. During the 1970–86 period, the overall proportion of low-birth-weight babies declined from 7.9 to 6.8 percent. All of this decline occurred between 1970 and 1980; since then there has been no change. Declines were observed for all age-of-mother groups, but the greatest reductions (19–21 percent) were for babies born to mothers in their thirties (table 13). In terms of birth weight, the ideal age of the mother has been 25–29 years during this period, but in 1986 births to women aged 30–34 years were only slightly more likely to be of low birth weight (6.1 compared with 6.0 percent).

When the comparisons are restricted to first births, the relationship of low birth weight to the age of the mother is similar, except that first births are at a somewhat higher risk of low birth weight than births of all birth orders combined for mothers who are aged 25 years or older. The decline in percent low birth weight for first births in the 1970–86 period also occurred during the 1970's. Since 1980, the only notable decline has been for first births to mothers aged 35–39 years, from 9.5 to 8.8 percent; the percent low birth weight for births to mothers in their forties increased.

First births to white and black mothers in their thirties are at greater risk in terms of low birth weight than those born to younger mothers, but this risk declined for both white and black babies during the 1970's. Still, first births born to black women in their thirties are about twice as likely as those born to white women to weigh less than 5½ pounds. This differential increased somewhat between 1970 and 1986.

The greater decline in the incidence of low birth weight among first births to mothers in their thirties compared with first births to younger mothers is probably a reflection of the changing characteristics of older first-time mothers. Prior to 1970, relatively few women were postponing motherhood until age 30 years or later. Rates of childlessness were very low and the few women who did have their first child after age 30 years probably did so not by choice but after many years of trying unsuccessfully to become pregnant or to carry a pregnancy to term. Since the early 1970's, more women have intentionally delayed childbearing.

The educational attainment of women who became mothers at relatively older ages has dramatically increased. Whereas in 1970 only about one-fourth of the women having their first child at age 30 years or older were college graduates, about one-half of their counterparts in 1986 had completed 4 years of college. Greater educational attainment in turn is associated with more timely receipt of prenatal care and a better outcome in terms of birth weight. For babies born to college graduates aged 30–34 years, only 5.8 percent were low birth weight compared with 7.5 percent for all first births to mothers in this age group (table 14). Comparison of each of the four age groups (ages 20–39 years) shows that the percent low birth weight for babies born to college graduates was 20–33 percent below the average for each age group. This helps explain the marked decline in levels of low birth weight among first births to mothers in their thirties.

The relationships between low birth weight and educational attainment of mother for white and black babies were similar. In every educational attainment category, however, first births to black mothers were at roughly twice the risk of weighing less than 2,500 grams as were first births to white mothers. Furthermore, within each age-of-mother group the racial differential in low birth weight generally increased with advancing educational attainment.

Prenatal care

As noted above, a major reason why first births to older mothers are at a relative advantage is the high level of educational attainment of these mothers, which in turn is a critical factor accounting for differentials in receipt of prenatal care. Older women who become pregnant are at a somewhat elevated risk of certain complications. Early receipt of prenatal care can help identify problems and provide the physician and the mother with the opportunity to treat them. In 1986, 94 percent of white and 86 percent of black mothers in their thirties who were college graduates began prenatal care in the first trimester. The distribution of first births for 1986 according to month of pregnancy in which prenatal care was begun is shown in table 15. Among white and black women having their first child, those in their early thirties were the most likely to receive prenatal care early and the least likely to have delayed care (beginning in the third trimester) or no care at all.

Advanced educational attainment and early receipt of prenatal care are in turn associated with favorable levels of low birth weight. Among births to women in their thirties with college degrees who began prenatal care in the first trimester, fewer than 5 percent weighed less than 5½ pounds in 1986. (Data are not shown in this report.) Even among the few college graduates whose care was delayed

until the second or third trimester, the proportion of low-birth-weight babies did not exceed 5.5 percent. These relationships are observed for white and black women, but in each age-educational attainment-prenatal care category, babies born to black women had more than twice the risk of low birth weight as babies born to white women.

Appendix

Technical notes

Sources of data

Data shown in this report for 1985 and 1986 are based on 100 percent of the birth certificates in all States and the District of Columbia. The data are provided to the National Center for Health Statistics (NCHS) through the Vital Statistics Cooperative Program (VSCP). Data for 1972–84 are based on 100 percent of the birth certificates from States participating in the VSCP and on a 50-percent sample of births from all other States. The number of States providing data through the cooperative program increased from 6 in 1972 to 46 in 1984. Data for 1970–71 are based on a 50-percent sample of births for all States. More detailed information on sampling procedures for 1970–84 is presented in the annual reports for those years—*Vital Statistics of the United States*, Volume I, “Nativity.”

Birth probabilities

Birth probabilities and proportions of women who are childless are derived from a specially prepared set of fertility tables for birth cohorts that are adjusted for under-registration of births and underenumeration of the population (NCHS, 1976). Because the data necessary to prepare these fertility tables were not available for the black population separately, these data were prepared for the white population and for the population of all other races as a group. The trends in first-birth rates for black and all other women were roughly parallel during the 1970's with the rates for black women running about 25 percent lower than the rates for all women other than white combined. In recent years, the trends have differed and the proportion of the all other population that is black has declined. Data for birth probabilities, birth rates, and proportions childless shown in figures 1–4 are derived from the specially prepared tables; the birth rates shown in tables 2 and 4 in this report are the regularly published period fertility rates, which are available for black women separately.

Educational attainment

To compute birth rates by age and educational attainment of mother for this report, two procedures were followed. For 1970 and 1975, it was necessary to estimate first births by age and educational attainment of mother for the United States as a whole from data reported by the States

that included information on educational attainment on their birth certificates. This was done by inflating the figures by educational attainment and age of mother for the reporting States to the known totals for each age group for the entire United States. Thus, for example, the distribution of births by educational attainment for mothers aged 20–24 years for the reporting States was applied to the United States total number of births to mothers aged 20–24 years to yield the estimated number of births by educational attainment for this age group. During the period 1970–75, the number of States reporting educational attainment increased from 38 (accounting for 67 percent of births in the United States) to 42 and the District of Columbia (accounting for 72 percent of total births).

For 1980 and 1985, special tabulations of the female population by age, race, and educational attainment were obtained from the U.S. Bureau of the Census for the total of 47 States and the District of Columbia that reported educational attainment on the birth certificate (excludes California, Texas, and Washington). The 1980 data are based on the 1980 census and were modified to be consistent with Office of Management and Budget categories of race. The modification procedures are discussed in detail in a U.S. Bureau of the Census (1982) report. The 1985 data are derived from the Current Population Survey conducted in June. (For information on fertility and educational attainment data obtained from this survey, see U.S. Bureau of the Census, 1986, 1987.)

Marital status

Beginning with 1980 data, national estimates of births to unmarried women are derived from two sources. For 41 States and the District of Columbia, marital status is reported directly on the birth certificate; for the remaining 9 States that lack such an item, marital status is inferred from a comparison of the child's and parents' surnames. This procedure represents a substantial departure from the method used prior to 1980 to prepare national estimates of births to unmarried women. The previous method assumed that the incidence of births to unmarried women in States with no direct question on marital status was the same as the incidence in reporting States in the same geographic division.

The current method represents an attempt to use related information on the birth certificate to improve the

quality of national data as well as to provide data for the individual nonreporting States. The method is based on a comparison of the child's surname, the mother's present and maiden surnames, and the father's surname. An evaluation of the new method and its continuing validity for California (the largest nonreporting State) has been published (NCHS, 1985).

Racial classification

The racial designation used in this report is that of the child, which is determined from the race of the parents as

entered on the birth certificate. When the parents are of different races and one parent is white, the child is assigned the other parent's race. When the parents are of different races and neither parent is white, the child is assigned the father's race with one exception: If the mother is Hawaiian or part Hawaiian, the child is considered Hawaiian. When the race of one parent is missing on the certificate, the child is assigned the race of the other parent. When race is not reported for either parent, the child is assigned the race of the child on the immediately preceding record.

Vital and Health Statistics series descriptions

- SERIES 1. Programs and Collection Procedures**—Reports describing the general programs of the National Center for Health Statistics and its offices and divisions and the data collection methods used. They also include definitions and other material necessary for understanding the data.
- SERIES 2. Data Evaluation and Methods Research**—Studies of new statistical methodology including experimental tests of new survey methods, studies of vital statistics collection methods, new analytical techniques, objective evaluations of reliability of collected data, and contributions to statistical theory. Studies also include comparison of U.S. methodology with those of other countries.
- SERIES 3. Analytical and Epidemiological Studies**—Reports presenting analytical or interpretive studies based on vital and health statistics, carrying the analysis further than the expository types of reports in the other series.
- SERIES 4. Documents and Committee Reports**—Final reports of major committees concerned with vital and health statistics and documents such as recommended model vital registration laws and revised birth and death certificates.
- SERIES 5. Comparative International Vital and Health Statistics Reports**—Analytical and descriptive reports comparing U.S. vital and health statistics with those of other countries.
- SERIES 6. Cognition and Survey Measurement**—Reports from the National Laboratory for Collaborative Research in Cognition and Survey Measurement using methods of cognitive science to design, evaluate, and test survey instruments.
- SERIES 10. Data From the National Health Interview Survey**—Statistics on illness, accidental injuries, disability, use of hospital, medical, dental, and other services, and other health-related topics, all based on data collected in the continuing national household interview survey.
- SERIES 11. Data From the National Health Examination Survey and the National Health and Nutrition Examination Survey**—Data from direct examination, testing, and measurement of national samples of the civilian noninstitutionalized population provide the basis for (1) estimates of the medically defined prevalence of specific diseases in the United States and the distributions of the population with respect to physical, physiological, and psychological characteristics and (2) analysis of relationships among the various measurements without reference to an explicit finite universe of persons.
- SERIES 12. Data From the Institutionalized Population Surveys**—Discontinued in 1975. Reports from these surveys are included in Series 13.
- SERIES 13. Data on Health Resources Utilization**—Statistics on the utilization of health manpower and facilities providing long-term care, ambulatory care, hospital care, and family planning services.
- SERIES 14. Data on Health Resources: Manpower and Facilities**—Statistics on the numbers, geographic distribution, and characteristics of health resources including physicians, dentists, nurses, other health occupations, hospitals, nursing homes, and outpatient facilities.
- SERIES 15. Data From Special Surveys**—Statistics on health and health-related topics collected in special surveys that are not a part of the continuing data systems of the National Center for Health Statistics.
- SERIES 16. Compilations of Advance Data From Vital and Health Statistics**—These reports provide early release of data from the National Center for Health Statistics' health and demographic surveys. Many of these releases are followed by detailed reports in the Vital and Health Statistics Series.
- SERIES 20. Data on Mortality**—Various statistics on mortality other than as included in regular annual or monthly reports. Special analyses by cause of death, age, and other demographic variables; geographic and time series analyses; and statistics on characteristics of deaths not available from the vital records based on sample surveys of those records.
- SERIES 21. Data on Natality, Marriage, and Divorce**—Various statistics on natality, marriage, and divorce other than as included in regular annual or monthly reports. Special analyses by demographic variables; geographic and time series analyses; studies of fertility; and statistics on characteristics of births not available from the vital records based on sample surveys of those records.
- SERIES 22. Data From the National Mortality and Natality Surveys**—Discontinued in 1975. Reports from these sample surveys based on vital records are included in Series 20 and 21, respectively.
- SERIES 23. Data From the National Survey of Family Growth**—Statistics on fertility, family formation and dissolution, family planning, and related maternal and infant health topics derived from a periodic survey of a nationwide probability sample of women 15–44 years of age.
- SERIES 24. Compilations of Data on Natality, Mortality, Marriage, Divorce, and Induced Terminations of Pregnancy**—Advance reports of births, deaths, marriages, and divorces are based on final data from the National Vital Statistics System and are published annually as supplements to the Monthly Vital Statistics Report (MVSR). These reports are followed by the publication of detailed data in Vital Statistics of the United States annual volumes. Other reports including induced terminations of pregnancy issued periodically as supplements to the MVSR provide selected findings based on data from the National Vital Statistics System and may be followed by detailed reports in Vital and Health Statistics Series.
