## GENERATION AND CURRENT LIFE TABLES

The mortality rates for a specific period may be summarized by the life-table method to obtain measures of comparative longevity. There are two types of life tables—the generation or cohort life table and the current or "snapshot" life table. The generation life table provides a "longitudinal" perspective in that it follows the mortality experience of an actual cohort—for example, all persons born in the year 1900—from the moment of birth through consecutive ages in successive years. Based on age-specific mortality rates observed during consecutive years, the generation life table reflects the mortality experience of a cohort from birth until no lives remain in the group.

The better known current life table may, by contrast, be characterized as "cross-sectional." Unlike the generation life table, the current life table considers a hypothetical cohort and assumes that it is subject throughout its existence to the age-specific mortality rates observed for an actual population during a particular period of relatively short duration (often 1 to 3 years).

## DECENNIAL LIFE TABLES FOR 1969-71

The life tables in this report are current life tables for the United States based on age-specific mortality rates for the period 1969-71. With the exception of those for ages 95 and over (and to a lesser extent those for ages 85-94), these mortality rates have been calculated from the data of the 1970 Census of Population and deaths occurring in the United States in the 3 years 1969-71. In deriving life-table values at ages under 2, reported births for each of the years 1967 to 1971 have also been used. Mortality rates at ages 95 and

over, where the data from the census and from registered deaths are scanty and unreliable, are based on the experience of the Medicare program. They were provided by the Office of the Actuary of the Social Security Administration, and thanks are due especially to Francisco Bayo, Deputy Chief Actuary, and Steven F. McKay, Actuary.

Tables 1-12 are life tables for white persons, the population other than white, and Negroes separately by sex and for both sexes combined and also for the total population and for total males and total females.

These tables are the most recent in a series of life tables that have been prepared at 10-year intervals for the death-registration States; the series began with those for 1900-1902. Each of the tables in the series is based on a census of population and deaths in a 3-year period containing the census year. These decennial life tables differ in two main respects from the life tables prepared and published annually in *Vital Statistics of the United States*; the annual tables are based on deaths in a single year and on postcensal population estimates rather than directly on the data of a decennial census, and the annual tables are calculated by abbreviated methods.

This report is the first of a series of reports containing life tables for 1969-71 and other information related to the decennial life-table program. Also included in the series will be a report containing actuarial tables based on the national life tables, 51 reports containing life tables for the individual States and the District of Columbia, a methodological report that will describe in detail the methods of construction of the national and State life tables, an analytical report dealing with trends and interpretations related to life expectancy and survivorship, and a report on life tables analyzed by major groups of causes of death.

## PRELIMINARY ADJUSTMENT OF DATA

These are the first decennial life tables for the United States in which it has not been found necessary to make any major ad hoc adjustments in the underlying data in order to avoid anomalies in the life-table values. (For example, in the 1959-61 tables, the population of races other than white at ages 55-64 was reallocated by age.)

However, certain minor adjustments have been incorporated. In accordance with standard practice, deaths for which age was not stated have been allocated proportionately among the various age groups. The population data used differ slightly from the official data published by the U.S. Bureau of the Census. Misunderstanding by some respondents of certain items in the self-enumeration form used in the 1970 census is believed to have produced (1) an overstatement of the number of centenarians, at the expense of all other age groups, and (2) an overstatement of the population of races other than white or Negro, at the expense of the white population.<sup>1</sup> Thanks are due to Jacob Siegel and Jerome Glynn of the Bureau of the Census for furnishing magnetic tapes containing special population data adjusted for these errors. These are the population data used in the preparation of the life tables contained in this report.

## MEASURES OF COMPARATIVE LONGEVITY

The life table provides a convenient tool for comparing the longevity of different populations or of different subdivisions of a population. The customary measure of longevity is the average duration of life, also called the expectation of life at birth. This is the average number of years lived by the members of the life-table cohort. Based on the mortality experience of 1969-71, the expectation of life at birth is 67.94 years for white males, 75.49 for white females, 60.00 for Negro males, and 68.32 for Negro females. These

---

<sup>1</sup> U.S. Bureau of the Census: Estimates of the population of the United States, by age, sex, and race, April 1, 1960, to July 1, 1973. *Current Population Reports*, Series P-25, No. 519. Washington. U.S. Government Printing Office, Apr. 1974. The types of errors mentioned are described on p. 8. Population data consistent with those used in preparing the life tables in this report appear in table 6, p. 70.

values reflect the higher mortality of males over females and of Negroes over white persons (except at older ages starting at about 75). Expectation of life at birth for white females is 7.55 years longer than for white males, and the corresponding excess for Negro females over Negro males is 8.32 years. It appears that sex has a greater influence on this statistic than race, since the expectation of life at birth for Negro females exceeds that for white males by 0.38 years.

Expectation of life at birth ( $e_x$ ) is strongly affected by the relatively large number of deaths occurring during the first year of life. In comparing the longevity of different populations, it may be desirable to consider also expectation of life at age 1 ( $e_1$ ), since this measure is not affected by the infant mortality rate. Indeed, as shown in tables 1-12,  $e_1$  is greater than  $e_0$  in all population groups; those persons in the hypothetical cohort who survive the hazards of infancy exhibit an increase in the average number of years of life remaining over the number expected when they were 1 year younger. The 1969-71 values of  $e_1$  are 68.33 years for white males, 75.66 for white females, 61.24 for Negro males, and 69.37 for Negro females. The increase in expectation of life at age 1 over age 0 is substantial for Negro males and females (1.24 and 1.05 years, respectively) but much less for white males and females (0.39 and 0.17 years, respectively); this reflects the higher infant mortality of the Negro population.

It may be of interest for certain purposes to examine average remaining lifetime at other ages. For example, ages 21, 62, and 65 may be regarded as representing, respectively, the attainment of adulthood, the minimum retirement age prescribed by the Social Security Act, and the normal retirement age. The 1969-71 values of expectation of life at age 21 are 49.32 for white males, 56.28 for white females, 42.65 for Negro males, and 50.28 for Negro females. Corresponding values for age 62 are 14.80, 19.22, 13.93, and 17.42 years; and for age 65 they are 13.02, 16.93, 12.53, and 15.67 years.

The concept of expectation of life is misleading if it is taken to imply the notion of forecasting. It is important to understand that expectation of life values forecast average remaining lifetime only for the hypothetical cohort of the

life table. Comparable forecasts for any actual population would have to take into account future mortality trends as well as current mortality rates.

Another possible yardstick for comparing the longevity of different populations is the median length of life, or "probable lifetime," which is the age at which exactly half the original members of the life-table cohort have died. When the cohort starts with 100,000 births, this would be the age at which there are just 50,000 survivors. Easily calculated from the  $l_x$  values in the life tables, the median length of life at birth, based on the mortality rates of 1969-71, is 71.55 years for white males, 79.45 for white females, 63.78 for Negro males, and 72.15 for Negro females. In calculating the median length of life, it is assumed that deaths are evenly distributed within the age interval containing the median age.

A comparison of the probable lifetime with the expectation of life at birth shows that the former exceeds the latter for each population

subgroup. Thus the median length of life at birth for 1969-71 is 3.61 years more than the expectation of life for white males; for white females, 3.96 years; for Negro males, 3.78; and for Negro females, 3.83. These differences are due to the asymmetrical, or skewed, character of the statistical distribution of deaths in the life-table cohort; the relatively large number of deaths in the first year of life plays a major role in producing this asymmetry.

Still another measure of comparative longevity is the number (or percentage) of persons in the original cohort surviving to a specified age. Such data are supplied by the  $l_x$  column of the life tables. Thus on the basis of 1969-71 mortality, the percentage of white males surviving to age 1 is 98.0; of white females, 98.5; of Negro males, 96.4; and of Negro females, 97.1. At age 21 the corresponding percentages are 96.3, 97.6, 93.7, and 95.6; and at age 65 they are 66.3, 81.6, 47.5, and 64.7.

## EXPLANATION OF THE COLUMNS OF THE LIFE TABLE

(Figures used for illustration are from table 6)

*Column 1—Age interval ( $x$  to  $x+t$ )*—The age interval shown in column 1 is the interval between two exact ages indicated. For instance, "7-28 days" means the 21-day interval between the exact ages of 7 days and 28 days, and "43-44 years" means the interval of 1 year between the 43d and 44th birthdays. In the life tables in this report the age interval is always 1 year except in the case of subdivisions of the first year of life.

*Column 2—Proportion dying ( $q_x$ )*—This column shows the proportion of the members of the life-table cohort alive at the beginning of the indicated age interval who will die before reaching the end of that age interval (in most instances, the next birthday) on the basis of the mortality rates of 1969-71. For example, for white females in the age interval 7-28 days, the proportion dying is 0.00115—out of every 1,000 white female babies surviving 7 days after birth, 1.15 will die before reaching the age of 28 days. Similarly, for white females in the age interval 43-44 years, the proportion dying is 0.00254—out of every 1,000 white females reaching their 43d birthday, 2.54 will die before reaching their 44th birthday. When the age interval is 1 year, the symbol  $q_x$  (instead of  ${}_1q_x$ ) is generally used for the proportion dying.

*Column 3—Number surviving ( $l_x$ )*—This column shows the number of persons, starting with a cohort of 100,000 live births, who will survive to the exact age marking the beginning of the indicated age interval. Thus out of 100,000 white female babies born alive, 98,944 will survive 7 days, 98,468 will complete the first year of life and enter the second, 97,555 will reach age 21, and 63,290 will live to age 75.

*Column 4—Number dying ( $d_x$ )*—This column shows the number dying in each successive age interval out of 100,000 live births. Thus out of 100,000 white females born alive, 114 will die between the ages of 7 and 28 days, 1,532 will die in the entire first year of life, and 242 in the year between their 43d and 44th birthdays. Evidently each figure in column 4 is the difference between two successive figures in column 3. When the age

interval is 1 year, the symbol  $d_x$  (instead of  ${}_1d_x$ ) is generally used for the number dying.

*Columns 5 and 6—Stationary population ( ${}_tL_x$  and  $T_x$ )*—Suppose that a group of 100,000 persons like that assumed in columns 3 and 4 is born every year and that the proportions dying in each such group in each age interval throughout the lives of the members are exactly those shown in column 2. If there were no migration and if the births were evenly distributed over the year, the survivors of these births would constitute what is called a stationary population—stationary because in such a population the number of persons living in any given age interval would never change. When an individual left an age interval, whether by death or by growing older and entering the next higher age interval, his place would immediately be taken by someone entering from the next lower age interval. Thus a census taken at any time in such a stationary community would always show the same total population and the same numerical distribution of that population among the various age intervals. In such a stationary population supported by 100,000 annual births, column 3 shows the number of persons who, each year, will reach the exact age that marks the beginning of the age interval indicated in column 1, and column 4 shows the number of persons who will die each year in the indicated age interval.

Column 5,  ${}_tL_x$ , shows the number of persons in the stationary population in the indicated age interval. For example, the figure shown for white females in the age interval 7-28 days is 5,690. This means that in a stationary population of white females supported by 100,000 annual births, and with proportions dying in each age interval always in accordance with column 2, a census taken on any date would show 5,690 persons between the exact ages of 7 and 28 days. Similarly, the number of white females in the year of age 43-44 is 95,035. Thus the stationary population described would always contain 95,035 persons between their 43d and 44th birthdays. When the age interval is 1 year, the symbol  $L_x$  is generally used instead of  ${}_1L_x$ .

Column 6,  $T_x$ , shows the total number of persons in the stationary population (column 5) in the indicated age interval and all subsequent age intervals. For example, in the stationary population of white females described in the preceding paragraph, column 6 shows that there would be at any given moment a total of 7,546,908 persons who had survived at least 7 days following birth and a total of 3,363,876 persons who had attained age 43. The population at all ages 0 and above (in other words, the total white female population of the stationary community) would be 7,548,810.

*Column 7—Average remaining lifetime( $e_x$ )*—The average remaining lifetime (also called expectation of life) at any given age is the average number of years remaining to be lived by those surviving to that age, on the basis of a given set of age-specific rates of dying. In order to relate these figures to the preceding columns of the life table it is necessary to observe that the figures in column 5 of the life tables can also be interpreted in terms of a single life-table cohort without introducing the concept of the stationary population. From this point of view, each figure in column 5 represents the total time (in years) lived between two indicated exact ages by all those reaching the younger age among the survivors of a cohort of 100,000 live births. Thus the figure of 5,690 for white females in the age interval 7-28 days is the total number of years of life lived between the exact ages of 7 and 28 days by the 98,944 (column 3) who reached the age of

exactly 7 days out of 100,000 white females born alive. The corresponding figure (7,546,908) in column 6 is the total number of years lived after attaining the age of 7 days by the 98,944 reaching that exact age. Similarly, the figure 95,035 in column 5 for white females in the year of life 43-44 is the total number of years lived between their 43d and 44th birthdays by the 95,156 (column 3) who reached the 43d birthday out of the original cohort of 100,000, and the corresponding figure (3,363,876) in column 6 is the total number of years lived after attaining age 43 by the 95,156 reaching that age.

This number of years divided by the number of persons (3,363,876 divided by 95,156) gives 35.35 years as the average remaining lifetime at age 43. A similar division of 7,546,908 by 98,944 gives 76.27 years as the average remaining lifetime at the age of 7 days.

Care must be exercised in drawing conclusions from the figures in column 7. Thus in observing that the average remaining lifetime of white persons is greater than that of Negroes, one should not conclude that the oldest ages reached by white persons necessarily exceed those attained by the most long-lived Negroes. The difference in average length of life results from the fact that a greater proportion of Negroes die before reaching old age. For example, the proportion surviving to age 65 is far greater among white persons than among Negroes; yet the average length of life remaining at age 65 is nearly the same for both groups.

TABLE 1. LIFE TABLE FOR THE TOTAL POPULATION: UNITED STATES, 1969-71

AGE INTERVAL	PROPORTION DYING	OF 100,000 BORN ALIVE		STATIONARY POPULATION		AVERAGE REMAINING LIFETIME
